1. Introduction

The mounting demands of energy due to increase in population and urbanization have put significant stress on conventional energy sources. Additionally, an increasing use of the fossil fuel-based energy sources has a devastating impact on the environment [1]. This situation calls for clean, renewable, and economically viable energy alternatives that would replace fossil fuels. Hydrogen stands out as a highly promising clean, renewable, and economically viable energy alternatives that are capable of storing practically meaningful volumetric and gravimetric amounts of hydrogens and releasing them on demand.

Among the various available options, carbonous materials possess a great potential for H2 storage applications due to their salient features like stability, cost-effectiveness, and porosity. H2 storage capacities of the host carbonous materials are further enhanced by increasing their surface areas such as via nanostructuring [12]. However, a downside of carbonous nanostructures is their weak, van der Waals type interactions with the incident H2 molecules, which allows for molecule storage only at very low temperatures [13–15]. For ambient condition storage applications, the binding energies of H2 to the host material should be close to 0.16 eV/H2 [16,17]. To enhance the interactions between H2 and the host carbonous nanostructures, the introduction of dopant atoms has been applied with promise [18–22].

In literature, several studies have been devoted to the study of H2 storage properties of the metalized carbonous nanostructures,
particularly the 2D monolayers [23–26]. A recent study explored the potential of metal-doped nitrogenated holey graphene (C2N) as H2 storage material [27]. The authors employed dispersion-corrected DFT simulations to study the adsorption of H2 molecules on C2N in its pristine and metal-decorated (e.g., Mg, Ca, Ti, V, Mn, Fe, Co, Ni, and Zn) forms. It was found that the pristine C2N’s weak hydrogen binding energy (0.10 eV/H2) is enhanced significantly after its decoration with metals. In another study, Chen et al. employed first-principles DFT calculations for the study of lithium functionalized graphitic carbon nitride (g-CN) monolayers for H2 storage [16]. They found that the Li atoms are strongly bonded to g-CN sheets without being clustered, therefore facilitating a rather uniform distribution of metal cations over the host material. Each Li+ cation interacted with multiple H2 molecules and that resulted in a H2 storage capacity of 10.8 wt% Hydrogen, which is larger than is possible for many other 2D systems, such as phosphorene and MoS2. Similarly, Faye et al. has recently reported the H2 storage properties of 2D carbon nitride, C3N, sheets through spin-polarized DFT simulations [28]. The structural and H2 adsorption properties of Si- and Ti-doped C3N nanosheets were studied in the context of ambient condition H2 storage. They found that the metal-doped C3N nanosheets were able to reach a high H2 storage capacity of 9.0 wt% Hydrogen. In addition to the above-mentioned theoretical reports, several experimental groups studied the potential of use different nanomaterials for H2 storage applications. In this regard, porous carbon-based structures [29,30], multilayered graphene [31] and Ti2C nanosheets [32] have recently been explored.

Motivated by the promise of peculiar carbonaceous nanostructures as discussed in the above studies, we employed DFT calculations to study the structural features and H2 storage properties of lightweight metal functionalized haeckelites (r57). We found that, the graphene-like open structure, but with 5- and 7-membered rings of carbon atoms, of the haeckelites enable strong interactions with metal adatoms, and they consequently attain good H2 storage properties.

2. Computational methods

All DFT calculations were carried out using the generalized gradient approximation (GGA) exchange-correlation functional of Perdew-Burke-Ernzerhof (PBE) [33] and the projector augmented wave (PAW) [34,35] method, as implemented in the Vienna ab initio simulation package (VASP) [36–38]. A plane wave basis with a kinetic energy cutoff of 600 eV was used. The H 1 s, B 2s2p, C 2s2p, Li 1s2s, Na 3s2p, K 3s3p4s, Ca 3s3p4s, Sc 3p4s3d and Ti 3p4s4d3 electrons were considered as valence. Spin-polarized calculations were performed within the framework of DFT and no charge or dipole correction procedures were applied [39]. The DFT-D3 scheme [40,41] was used to account for the dispersion interactions, which provides accurate results for molecule storage systems [42–45].

The original structural parameters of r57 were obtained from literature [46] and the structure was further optimized with the above settings and a vacuum spacing of 20 Å to avoid interactions between periodic images. Using the f-centred Monkhorst–Pack scheme [47] with a 7 × 9 × 1 k-mesh for the unit cell, the geometries were fully optimized until the total forces acting on each atom were smaller than 0.01 eV Å. The isolated H2 molecule was calculated by using a 20 Å edge cubic box with periodicity.

We calculated the binding energy of metal atoms to the host sheet, as follows

\[
E_b^{\text{ave}} = \frac{(nE_M + E_{\text{host}} - E_{\text{host-M}})}{n}
\]

where \(E_M\) is the total energy of one metal atom in its respective metal crystal, \(E_{\text{host}}\) and \(E_{\text{host-M}}\) are the total energies of the host simulation cells prior and posterior to metal decoration, respectively.

The average adsorption energy (\(E_{\text{ave}}\)) and the consecutive adsorption energy (\(E_{\text{con}}\)) of H2 molecules to the host materials were defined as

\[
E_b^{\text{ave}} = \frac{(nE_M + E_{\text{host}} - E_{\text{host-M}})}{n}
\]

where \(E_M\) is the total energy of a H2 molecule in gas phase, \(E_{\text{host-M}}\) and \(E_{\text{host}}\) are the total energies of the host sheets with \((n-1)\) and \(n\) H2 molecules, respectively.

3. Results and discussions

The optimized structure of the r57 monolayer is shown in Fig. 1(a). The optimized lattice constants of the unit cell are \(a = 7.47\) and \(b = 5.86\) Å, with the C–C bond lengths altering between 1.39 and 1.49 Å. These parameters agree well with the literature [46].

To investigate the interaction of H2 with the r57 sheet, four different kinds of adsorption sites were considered: top of C atoms (C7), top of C–C bonds (C8), top of 5-atom ring centres (F1), and top of 7-atom ring centres (S1). The lowest energy configuration is found to be when the H2 molecules are positioned at S1 sites, with \(E_b^{\text{ave}} = 0.07\) eV, which indicates a weak interaction between the 2D material and H2 molecules. For efficient hydrogen storage, the binding interactions of hydrogen molecules on pure r57 sheets would have to be improved, such as through the incorporation of lightweight metal atoms to the host material.

Similar to the procedure for hydrogen molecules interacting with the 2D material, for the metal atoms, we also considered different adsorption sites on the r57 sheet. For all metals, the lowest energy adsorption site is predicted to be the S7 site and the calculated binding energies of the metal atoms on r57 are shown in Table 1. The \(E_b^{\text{ave}}\) for Li, Na, and K is positive, meaning that these alkali metals adsorb stably on the r57 sheet, whereas Ca decoration is prone to metal clustering as evident from the negative \(E_b^{\text{ave}}\). Next, we focus on the most promising alkali metal loadings of r57-Li4, r57-Na4, and r57-K3 as host materials for H2 molecules. The optimized structures prior and posterior to full hydrogen loading are shown in Fig. 2. We found that each Li, Na, and K on r57 interact with three H2 molecules with \(E_b^{\text{ave}}\) of 0.18, 0.19, and 0.18 eV/H2, respectively. On r57-Li4, a fourth H2 molecule is accommodated with a moderate \(E_{\text{con}}\) of 0.13 eV/H2. However, as shown in Fig. 2(a), it is positioned relatively further away from the Li atom. Similarly, the fourth H2 molecule binds with \(E_{\text{con}}\) of 0.16 and 0.12 eV/H2 on r57-Na3 and r57-K1, respectively. The fifth H2 molecule adsorbs onto the metal atoms of r57-Na3 (Fig. 2(b)) and r57-K1 (Fig. 2(c)), but only via weak interactions of 0.08 eV/H2 and 0.06 eV/H2, respectively. For all these considered cases of alkali metal modified matrix, the maximum effective hydrogen storage capacity is 3.6 wt% H2 (for r57-Na4H4), which is lower than the 5.5 wt% storage target as set by the U. S. Department of Energy (DOE) [48].

To enhance the hydrogen storage capacity of r57 sheets, an increased amount of dispersed metal ions is required on their surface. Earlier theoretical studies show that incorporating B atoms into graphene provides a way for immobilizing metal atoms on its surface [49]. Additionally, taking into account that B-doped graphene monolayers are experimentally realized [50], we also study here the B doping of r57. All the three unique C atoms of r57 unit cell, as illustrated in Fig. 1(a), were considered in turn for the atomic substitutions with B. The most stable

![Fig. 1](image-url)
configuration, B@r57, is reached when a B atom substitutes C1 atom, as shown in Fig. 1 (b). Next, we studied the adsorption of a H2 molecule on B@r57, and found that the molecule tends to reside at S1 site with a binding energy of 0.07 eV/H2, which is both positionally and energetically very similar to the hydrogen molecule on the pure r57 sheet.

The calculated adsorption energies of different metal atoms on B@r57 are shown in Table 1. According to these results, when compared with r57, the B@r57 has stronger interactions with the metal atoms. Interestingly, all metal atoms at any of the considered loading ratios in the current study, have positive binding energies on B@r57. Furthermore, according to Bader charge analysis results of the B@r57-Mx compounds (M = Li, Na, K, and Ca; n = 1, 4, and 8), shown in Table 2, all metal atoms on B@r57 monolayers were depleted. However, with an increase in the number of adsorbed metal atoms in the simulation cell, the average electrical charge of metal atoms decreased. Among the metals studied here, the change of charge depletion was lowest for Li, meaning that, Li atoms were electrically the least affected by an increase in metal population on B@r57 monolayers.

Next, we discuss the hydrogen storage performances of the M-decorated B@r57 sheets.

Table 1
The calculated binding energies (E_b) of metal atoms on host materials, r57 and B@r57, under different metal loading conditions. All units are given in eV/M.

Fig. 2. The most stable structures of r57-M1 and r57-M4H2, where M is (a) Li, (b) Na and (c) K. Brown, blue, golden, purple and white spheres represent C, Li, Na, K, and H atoms, respectively. For clarity, on each compound, the relatively weakly binding H2 molecules, which have the lowest E_b, and are furthest away from the metal atoms, have been encircled. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
Li decoration: For one-, four-, and eight-Li atom decorations, the most stable geometries of the compounds are shown in Fig. 3 (a)-(c), with the corresponding $E_b^{\text{Li}} = 0.86$, 0.20, and 0.02 eV/Li, respectively. Considering both $E_b^{\text{Li}}$ and steric suitability for molecular hydrogen interactions, the four-Li atom decorated B@r$_{57}$ compound, B@r$_{57}$-Li$_4$, provides a good balance of metal loading for hydrogen storage purposes. To further illustrate the stability of B@r$_{57}$-Li$_4$, we carried out ab initio molecular dynamics (AIMD) calculations [51] on the corresponding $2 \times 2 \times 1$ supercell. Fig. 4 shows the structures at the end of 10 ps AIMD calculations that were performed at four different temperatures of 200, 300, 400, and 500 K. Although the Li atoms became more mobile with an increase in temperature, they still were attached to the 2D material even at elevated temperatures. Moreover, we studied the cases when each Li attracts one, two, and three H$_2$ molecules, and found that B@r$_{57}$-Li$_4$ efficiently adsorbed a total of 12 H$_2$ molecules with $E_b^{\text{H}_2} = 0.16$ eV/H$_2$. Accordingly, the hydrogen storage capacity of B@r$_{57}$-Li$_4$ reached to 10.0 wt% H$_2$.

Na/K decoration: Either of the single Na and K atom decorated B@r$_{57}$ compounds adsorbed four H$_2$ molecules to the most, with $E_b^{\text{H}_2} = 0.17$ eV/H$_2$ and 0.14 eV/H$_2$, respectively. For four-Na or four-K decorated B@r$_{57}$, the interactions between H$_2$ molecules and Na/K surface atoms were weak (e.g. $E_b^{\text{H}_2} = 0.08$ eV/H$_2$ for B@r$_{57}$-Na$_4$H$_4$). These results were in relation to the relatively inefficient discharge of these atoms ($Q_e^{\text{Na}} = +0.60$ [e], $Q_e^{\text{K}} = +0.50$ [e]) after their deposition onto the B@r$_{57}$ monolayers.

Ca decoration: The Ca atom of the B@r$_{57}$-Ca$_4$ compound effectively adsorbed up to five H$_2$ molecules with $E_b^{\text{H}_2} = 0.21$ eV/H$_2$. However, when the number of Ca atoms increased to four to form the B@r$_{57}$-Ca$_4$ compound, then each Ca interacted with a maximum of four H$_2$ molecules and with $E_b^{\text{H}_2} = 0.12$ eV/H$_2$. Nevertheless, this compound still reached to a hydrogen storage capacity of 8.4 wt% H$_2$.

The metal ions of the B@r$_{57}$-M$_1$ compounds interact with only three to five H$_2$ molecules, whereas for the B@r$_{57}$-M$_4$ compounds, the distances between neighbouring metal atoms are comparable to the respective M-M distances found in their bulk metal crystal structures. Additionally, for the latter compounds, the calculated absolute Bader charge values of metal ions were small. Thus, due to steric and electronic effects, these compounds are not the most interesting compositions for hydrogen storage. Based on these findings, the B@r$_{57}$-Li$_4$ compound is the most promising candidate for molecular hydrogen storage. Therefore, to provide a versatile insight into the nature of interactions between H$_2$ molecules and B@r$_{57}$-Li$_4$, we further studied their electronic properties.

Fig. 5 shows the optimized geometry of the fully hydrogen loaded B@r$_{57}$-Li$_4$H$_{24}$ compound and its corresponding electron localization function (ELF), both as calculated using DFT. Clearly, all Li atoms were exposed on the B@r$_{57}$ monolayer and they were electrically depleted.

Fig. 3. The top and side views of the DFT optimized structures of (a) B@r$_{57}$-Li$_1$, (b) B@r$_{57}$-Li$_4$, and (c) B@r$_{57}$-Li$_4$ compounds.

Fig. 4. The snapshots from the side view of the $2 \times 2 \times 1$ B@r$_{57}$-Li$_4$ supercell, as obtained at the end of 10 ps AIMD simulations at $T = 200$, 300, 400, and 500 K, respectively from (a) to (d).

Moreover, Li atoms had no apparent orbital interactions with either of the B@r$_{57}$ monolayer or the H$_2$ molecules that were positioned around them. The localized electron clouds surrounding the H$_2$ molecules showed no evidence of orbital interactions with the atoms of the host material. The electronic density of states (DOS) calculations were also used to investigate the B@r$_{57}$-Li$_4$ compounds. As shown in Fig. 6 (a) DOS plot of the pure B@r$_{57}$ monolayer, the bonding contributions were mainly from the $p$ orbitals of C and B atoms. When Li dopants were added onto the monolayer, their valance $s$ electrons were transferred to the host material and no strong orbital interactions were evident between Li and monolayer C or B atoms (Fig. 6 (b)). Instead, the charge transfer from Li atoms to the 2D material results in an increased density for the occupied states of C and B atoms, which indicates ionic bonding between the metal and nonmetal atoms of B@r$_{57}$-Li$_4$. Fig. 6 (c) shows the DOS for the fully hydrogenated B@r$_{57}$-Li$_4$ compound. The adsorbed H$_2$ molecules on the monolayer populate around ~9 eV, and they showed no real influence on the valance states of C, B, and Li atoms. The calculated DOS data is consistent with the above discussed ELF and atomic charge analysis results.

4. Conclusions

In summary, the adsorption of H$_2$ molecules on lightweight metal atom decorated haeckelites was studied by first-principles DFT calculations. We found that H$_2$ molecules interact weakly with pristine r$_{57}$ and B-doped B@r$_{57}$ haeckelites. With the introduction of alkaline and alkaline earth metals, the binding energies of hydrogen molecules were improved. When compared with pure r$_{57}$, the B@r$_{57}$ haeckelites were more useful in immobilizing the metal atoms, and hence more successful in reaching to high hydrogen storage capacities. Of the metal decorated B@r$_{57}$ systems investigated here, the B@r$_{57}$-Li$_4$ compound is the most promising candidate for practical usage, as it yielded the highest hydrogen storage capacity of 10.0 wt% H$_2$ at a hydrogen binding energy of 0.16 eV/H$_2$. A further analysis of the electronic structures revealed that the interactions between the protruding Li atoms of the B@r$_{57}$-Li$_4$ compound and the H$_2$ molecules were mainly electrostatic by nature.
